Linear mediation and moderation

Session 12

MATH 80667A: Experimental Design and Statistical Methods HEC Montréal

Outline

Linear mediation model

Moderation

Linear mediation

Reminder: three types of causal associations

Confounding

Causation

Collision

Common cause

Causal forks $X \leftarrow Z \rightarrow Y$

Mediation

Causal chain $X \rightarrow Z \rightarrow$

Selection / endogeneity

inverted fork $X \rightarrow Z \leftarrow Y$

We are interested in **mediation**.

Notation

Define

- ullet treatment of individual i as X_i , typically binary with $X_i \in \{0,1\}$ and
 - $\circ~X=0$ (control), else $X=x_0$
 - $\circ X = 1$ (treatment)
- ullet potential mediation given treatment x as $M_i(x)$ and
- ullet potential outcome for treatment x and mediator m as $Y_i(x,m)$.

Sequential ignorability assumption

1. Given pre-treatment covariates Z, potential outcomes for mediation and treatment are conditionally independent of treatment assignment.

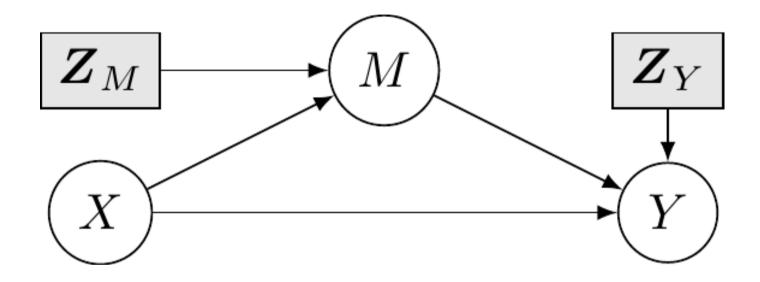

$$Y_i(x',m), M_i(x) \perp \!\!\! \perp X_i \mid oldsymbol{Z}_i = oldsymbol{z}_i$$

2. Given pre-treatment covariates Z and observed treatment x, potential outcomes for the response are independent of mediation.

$$Y_i(x',m) \perp \!\!\! \perp M_i(x) \mid X_i = x, oldsymbol{Z}_i = oldsymbol{z}_i$$

- Assumption 1 holds under randomization of treatment.
- ullet Assumption 2 implies there is no confounder affecting both Y_i, M_i .

Directed acyclic graph

Directed acyclic graph of the linear mediation model

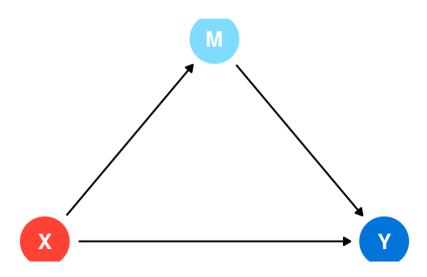

Total effect

Total effect: overall impact of X (both through M and directly)

$$\mathsf{TE}(x,x_0) = \mathsf{E}[Y \mid \mathrm{do}(X=x)] - \mathsf{E}[Y \mid \mathrm{do}(X=x_0)]$$

This can be generalized for continuous X to any pair of values (x_1,x_2) .

$$X \rightarrow M \rightarrow Y$$
plus
 $X \rightarrow Y$

Average controlled direct effect

$$\mathsf{ACDE}(m,x,x_0) = \mathsf{E}\{Y_i(x,m) - Y_i(x_0,m)\} \ = \mathsf{E}\{Y \mid \mathrm{do}(X=x,m=m)\} - \mathsf{E}\{Y \mid \mathrm{do}(X=x_0,m=m)\}$$

The average controlled direct effect (ACDE) is the expected change in response for the population when

- ullet the experimental factor changes from x to x_0 and
- ullet the mediator is set to a fixed value m

This typically requires experimental manipulation of both variables.

Direct and indirect effects

Natural direct effect: the expected change in Y under treatment x if M is set to whatever value it would take under control x_0

$$\mathsf{NDE}(x,x_0) = \mathsf{E}[Y\{x,M(x_0)\} - Y\{x_0,M(x_0)\}]$$

Natural indirect effect: the expected change in Y if we set X to its control value and change the mediator value which it would attain under x

$$\mathsf{NIE}(x,x_0) = \mathsf{E}[Y\{x_0,M(x)\} - Y\{x_0,M(x_0)\}]$$

Counterfactual conditioning reflects a physical intervention (experimentation), not mere conditioning.

Necessary and sufficiency of mediation

From Pearl (2014):

The difference $\mathsf{TE} - \mathsf{NDE}$ quantifies the extent to which the response of Y is owed to mediation, while NIE quantifies the extent to which it is explained by mediation. These two components of mediation, the necessary and the sufficient, coincide into one in models void of interactions (e.g., linear) but differ substantially under moderation

The Baron-Kenny linear mediation model

Consider the following two linear regression models with a binary treatment $X \in \{0,1\}$ and M binary or continuous:

$$M = c_M + lpha X + arepsilon_{M} \ ext{mediator} \ ext{intercept} \ ext{error term}$$

We assume that zero-mean error terms ε_M and ε_Y are **uncorrelated**.

This is tied to the no confounders assumption.

Total effect decomposition

Plugging the first equation in the second, we get the marginal model for \boldsymbol{Y} given treatment \boldsymbol{X}

$$\mathsf{E}(Y \mid X = x) = (c_Y + \gamma c_M) + (eta + lpha \gamma) \cdot x$$
 intercept total effect

In an experiment, we can obtain the total effect via the ANOVA model, with

$$Y = egin{array}{cccc}
u & + & au X + & arepsilon_{Y'} \ {
m average \ of \ control} & {
m total \ effect} & {
m error \ term} \ \end{array} \ au = {
m E}\{Y \mid {
m do}(X=1)\} - {
m E}\{Y \mid {
m do}(X=0)\}$$

Example from Preacher and Hayes (2004)

Suppose an investigator is interested in the effects of a new cognitive therapy on life satisfaction after retirement.

Residents of a retirement home diagnosed as clinically depressed are randomly assigned to receive 10 sessions of a new cognitive therapy (X=1) or 10 sessions of an alternative (standard) therapeutic method (X=0).

After Session 8, the positivity of the attributions the residents make for a recent failure experience is assessed (M).

Finally, at the end of Session 10, the residents are given a measure of life satisfaction (Y). The question is whether the cognitive therapy's effect on life satisfaction is mediated by the positivity of their causal attributions of negative experiences."

Old method

This approach has been discontinued, but still appears in older papers.

Baron and Kenny recommended running three linear regressions and testing

- 1. whether $\mathcal{H}_0: \alpha=0$
- 2. whether $\mathcal{H}_0: \tau=0$ (total effect)
- 3. whether $\mathcal{H}_0: \gamma=0$

The average conditional mediation effect (ACME) in the linear mediation model is $\alpha\gamma$ and we can check whether it's zero using Sobel's test statistic.

Problems with Baron-Kenny approach

- We conduct three tests, so this inflates the Type I error.
- The total effect can be zero because $\alpha \gamma = -\beta$, even if there is mediation.
- The method has lower power to detect mediation when effect sizes are small.

Sobel's test

Based on estimators of coefficients $\widehat{\alpha}$ and $\widehat{\gamma}$, construct a test statistic

$$S = rac{\widehat{lpha}\widehat{\gamma} - 0}{\mathsf{se}(\widehat{lpha}\widehat{\gamma})}$$

The coefficient and variance estimates can be extracted from the output of the regression model.

In large sample, $S \sim \mathsf{No}(0,1)$, but this approximation may be poor in small samples.

Other test statistics

Sobel's test is not the only test. Alternatives are discussed in

MacKinnon, D. P., Lockwood, C. M., Hoffman, J. M., West, S. G., & Sheets, V. (2002). A comparison of methods to test mediation and other intervening variable effects. Psychological Methods, 7(1), 83–104. https://doi.org/10.1037/1082-989X.7.1.83

Alternative

An alternative to estimate *p*-value and the confidence interval is through the nonparametric **bootstrap** with the percentile method, popularized by Preacher and Hayes (2004)

Nonparametric bootstrap: repeat B times, say $B=10\ 000$

- 1. sample n (same as original number of observations) tuples (Y_i, X_i, M_i) from the database **with replacement** to obtain a new sample.
- 2. recalculate estimates $\widehat{\alpha}^{(b)}\widehat{\gamma}^{(b)}$ for each bootstrap dataset

Boostrap confidence intervals

Percentile-based method: for a equitailed 1-lpha interval

- 1. Run the nonparametric bootstrap and obtain estimates $\widehat{\alpha}^{(b)}$ and $\widehat{\gamma}^{(b)}$ from the bth bootstrap sample.
- 2. Compute the lpha/2 and 1-lpha/2 empirical quantiles of

$$\{\widehat{lpha}^{(b)}\widehat{\gamma}^{(b)}\}_{b=1}^{B}.$$

Boostrap two-sided p-value

Compute the sample proportion of bootstrap statistics that are larger/smaller than zero.

- 1. Order bootstrap statistics $S^{(1)} \leq \cdots \leq S^{(B)}$ and let $S^{(0)} = -\infty$, $S^{(M+1)} = \infty$.
- 2. Find M ($0 \leq M \leq B$) such that $S^{(M)} < 0 \leq S^{(M+1)}$ (if it exists)
- 3. The p-value is

$$p = 2 \min\{M/B, 1 - M/B\}.$$

Model assumptions

Same assumptions as analysis of variance and linear models

- Linearity of the mean model
 - \circ residual plots, fitted values \hat{y} against m and x
- Independent/uncorrelated errors
 - o no confounding, lack of serial correlation (e.g., cross-panels)
- Equal variance of errors in each model (homoskedasticity)
- Large samples

Causal assumptions

Conclusions about mediation are valid only when causal assumptions hold.

Assuming that X is randomized, we need

- ullet Lack of interaction between X and M
 - can be added to model, then use NID definition
- ullet Causal direction: M o Y M is an antecedent cause
 - $\circ \,\, M$ must be measured before Y
- ullet Reliability of M (no measurement error)
- ullet No confounding between X and M
 - can be included, but not mediators/colliders + correct form
- effect constant over individuals/levels

Sensitivity analysis

The no-unmeasured confounders assumption should be challenged.

One way to assess the robustness of the conclusions to this is to consider correlation between errors, as (e.g., Bullock, Green and Ha, 2010)

$$\mathsf{E}(\widehat{\gamma}) = \gamma + \mathsf{Cov}(arepsilon_M, arepsilon_Y) / \mathsf{Va}(arepsilon_M)$$

- We vary $ho={\sf Cor}(arepsilon_M,arepsilon_Y)$ to assess the sensitivity of our conclusions to confounding.
- The medsens function in the **R** package mediation implements the diagnostic of Imai, Keele and Yamamoto (2010) for the linear mediation model.

Defaults of linear mediation models

- Definitions contingent on model
 - (even if causal quantities have a meaning regardless of estimation method)
- It is possible to weaken assumptions (at the expense of more complicated models)
- Most papers do not consider confounders, or even check for assumptions
- Generalizations to interactions, multiple mediators, etc., requires care

Moderation

Moderator

A **moderator** W modifies the direction or strength of the effect of an explanatory variable X on a response Y (interaction term).

Directed acyclic graph of moderation

Mediators in a linear regression model

In a regression model, we simply include an **interaction** term to the model between W and X.

For example, if X is categorical with K levels and W is binary or continuous, imposing sum-to-zero constraints for α_1,\ldots,α_K and β_1,\ldots,β_K gives

$$\mathrm{E}(Y \mid X = k, W = w) = \alpha_0 + \alpha_k + (\beta_0 + \beta_k)$$

average response of group k at w intercept of group k slope of group k

Testing for the interaction

Test jointly whether coefficients associated to XW, $\beta_1=\dots=\beta_K$ are zero. The mediator W can be continuous or categorical with $M\geq 2$ levels The F test has

- K-1 (continuous W- are slopes parallel?)
- (K-1) imes (M-1) (categorical W are all subgroup averages the same?)

Example

We consider data from Garcia et al. (2010), a study on gender discrimination. Participants were given a fictional file where a women was turned down promotion in favour of male colleague despite her being clearly more experimented and qualified.

The authors manipulated the decision of the participant, with choices:

- not to challenge the decision (no protest),
- a request to reconsider based on individual qualities of the applicants (individual)
- a request to reconsider based on abilities of women (collective).

The postulated mediator variable is sexism, which assesses pervasiveness of gender discrimination.

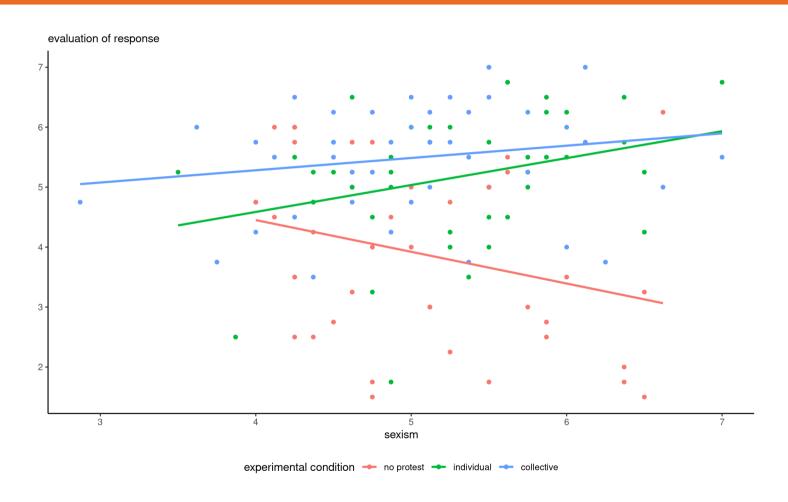

Model fit

We fit the linear model with the interaction and display the observed slopes

ANOVA table

term	sum of squares	df	stat p-value
protest	6.34	2	2.45 .091
sexism	6.59	1	5.09 .026
protest:sexism	12.49	2	4.82 .010
Residuals	159.22	123	

Effects

Results won't necessarily be reliable outside of the range of observed values of sexism.

Comparisons between groups

Simple effects and comparisons must be done for a fixed value of sexism (since the slopes are not parallel).

The default value in emmeans is the mean value of sexism, but we could query for averages at different values of sexism (below for empirical quartiles).

With mediating *factors*, give weights to each sub-mean corresponding to the frequency of the mediator rather than equal-weight to each category (weights = "prop").

Sensitivity analysis

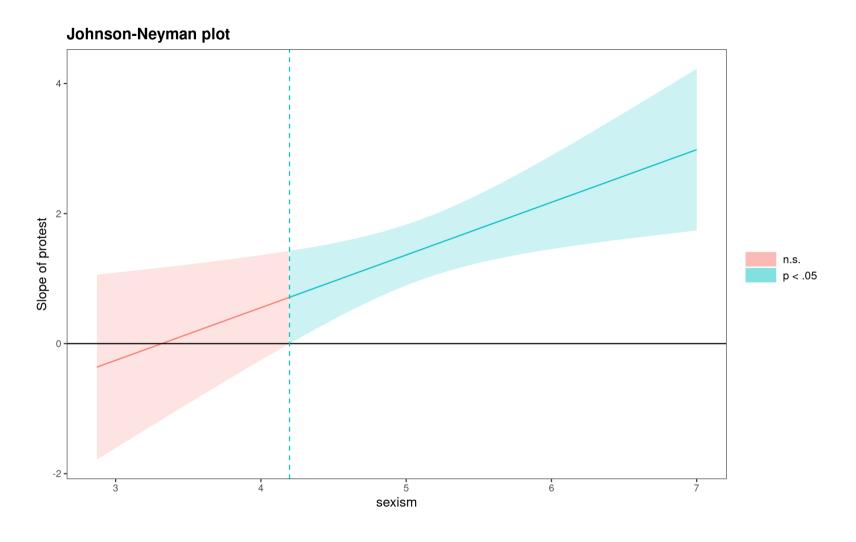

The Johnson and Neyman (1936) method looks at the range of values of mediator W for which difference between treatments (binary X) is not statistically significant.

Johnson, P. O., & Fay, L. C. (1950). The Johnson-Neyman technique, its theory and application. Psychometrika, 15(4), 349–367. doi:10.1007/bf02288864

```
lin_moder2 <- lm(
  respeval ~ protest*sexism,
  data = GSBE10 |>
  # We dichotomize the manipulation, pooling protests together
  dplyr::mutate(protest = as.integer(protest != "no protest")))
# Test for equality of slopes/intercept for two protest groups
anova(lin_moder, lin_moder2)
# p-value of 0.18: fail to reject individual = collective.
```

Syntax for plot

```
jn <- interactions::johnson_neyman(
   model = lin_moder2, # linear model
   pred = protest, # binary experimental factor
   modx = sexism, # moderator
   control.fdr = TRUE, # control for false discovery rate
   mod.range = range(GSBE10$sexism)) # range of values for sexism
jn$plot</pre>
```

Johnson-Neyman plot for difference between protest and no protest as a function of sexism.

Model assumptions and extensions

Interactions are not limited to experimental factors: we can also have interactions with confounders, explanatories, mediators, etc.

- Linearity assumption implies model is correctly specified. Need this to hold for inference to be approximately valid.
- ullet The case where interactions between XW o M and/or MW o Y in a mediation analysis is called moderated mediation".
